The problem, generic objectness proposal, aims to reduce the candidate windows for object detection tasks. The popular evaluation criterion for related methods is detection-rate/windows-amount (DR/#WIN), where DR is the percentage of groundtruth objects covered by proposal windows. An object is considered “covered” by a window only if the strict PASCAL-overall criterion [3] is satisfied (the intersection of a proposal window and the object rectangle is not smaller than half of their union, so we call it “0.5-criterion” for short). Under the DR/#WIN evaluation framework, BING [2] in CVPR2014, obtains the best performance on the VOC2007 test set. It recalls 96.2% objects with only 1,000 proposal windows. The more surprising is the method is totally a realtime one.

The authors of BING suggest that, after being resized to a fixed size (8 × 8), almost all annotated rectangle regions share a common characteristic in gradients [2]. This commonness is captured by a template view of combinatorial geometry. We try to construct a small set of windows for specific images. To sum up, what can we benefit from the two schemes for object detection researches? We argue it needs a bigger picture to answer this question because it depends on whether the 0.5-criterion is effective and objective. If the 0.5-criterion is still adopted in future, the baseline should be RAND-SCORE or our hybrid scheme instead of random guesses. Both of them bring more challenges to future researches.

Figure 1: Experiments on templates in BING: (a) four learned/hand-tuned templates and their performances. (b) performance of RAND-SCORE.

\[ \sum_{i \in k} \sum_{j=1}^{n-1} x(i, j) = \sum_{i=1}^{m-k-n} \sum_{j=1}^{n} \left( \frac{2^i - 1}{\sqrt{2} - 1} \right) \cdot \left( \frac{2^j - 1}{\sqrt{2} - 1} \right) = O(2^{2k} \cdot MN) \] (1)

Particularly, when the widths/heights of all object rectangles are at least 16, the amount is 19,600. While on the restriction of 32, we need only 4,225 windows. These amounts are far less than what people imagined before. We call it the Achilles’ heel of the DR/#WIN evaluation framework. Recall that in BING, the widths/heights of proposal windows are doubled each time, in the same way as in Lemma 3.1-3.4. Its non-max suppression step, 0.25 relative to the normalized size 8, is very close to the step \((1 - \frac{2}{3})^2 \approx 0.29\) in Lemma 3.2. These two settings meet our analysis well and bring the success to BING.

In real applications, we should pay more attention to those “hot” locations/sizes instead of all possibilities. We designed a greedy scheme to pick the “hottest” window in each round to construct an identical cover for all images. We also proposed a hybrid scheme to address the huge difference between low-probability sample spaces of the training and test sets. With the increase of the number of proposal windows, we replace the windows in the greedy set with those of RAND-SCORE with increasing probabilities.

In our experiments, our greedy scheme performs considerably well: all full cover sets are reduced to about 1,000 windows, and the first windows have 0.3+ DR’s in all experiments. In most time, the DR’s of our hybrid scheme are higher than OBN and SVM, and close to SEL and BING. It recalls 95.68% objects with 1000 proposal windows. Especially, its DR’s are 13.99% ~ 40.29% (relatively) higher than all other methods in average on the first ten windows. At last, the time consumptions are all nearly zero because the major computations are to resize proposal windows for specific images.
